Credit Card Fraud DetectionCapstone Project

Ricky J. Sparks

April 30th 2019

Project Overview

Fraud detection is a serious problem of the modern world. The news reports on countless attacks of credit card information being stolen annually. The transactions of fraudulent cards might seem minimal in occurrence but, on a larger scale these small

occurrences can cost companies millions in losses. This is where machine learning comes into play learning from the patterns and adapting to new possible schemes.

Machine learning can give credit card companies the ability to recognize fraudulent credit card transactions so that customers are not charged for items that they did not purchase.

Problem Statement

The problem presented is analyzing historical data of credit card transactions that were fraudulent and cards that weren't fraudulent. The goal of this model is to predict future transactions as fraud. The model will implement machine learning algorithms on the dataset that will ultimately lead us to an optimal algorithm that performs superior to the others. It is important that this model identifies most if not all of the fraud transactions with as much accuracy as possible. Thus, the nature of this problem is binary in nature as 0 represents valid transactions and 1 represents fraud transactions.

Metrics

This model should be expected as a high recall model since the nature of the problem is to catch more importantly fraudulent transactions even if the model has to sacrifice a small amount of valid transactions being misclassified as fraud. All in all, the metric recall should be represented in this model as a main metric.

Analysis

Data Exploration

The datasets contains transactions made by credit cards in September 2013 by european

cardholders. This dataset presents transactions that occurred in two days, where we

have 492 frauds out of 284,807 transactions. The dataset is highly unbalanced, the

positive class (frauds) account for 0.172% of all transactions.

It contains only numerical input variables which are the result of a PCA transformation.

Unfortunately, due to confidentiality issues, we cannot provide the original features and

more background information about the data. Features V1, V2, ... V28 are the principal

components obtained with PCA, the only features which have not been transformed with

PCA are 'Time' and 'Amount'. Feature 'Time' contains the seconds elapsed between each

transaction and the first transaction in the dataset. The feature 'Amount' is the

transaction Amount, this feature can be used for example-dependant cost-senstive

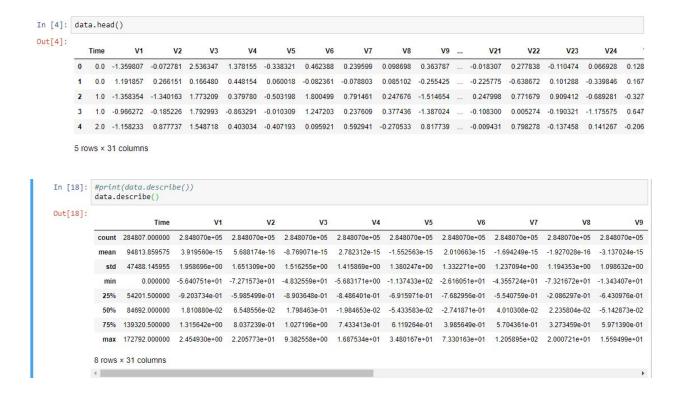

learning. Feature 'Class' is the response variable and it takes value 1 in case of fraud and

o otherwise.

3

Dataset Stats below

Exploratory Visualization

The histogram graph above as one can see shows how much the data is greatly skewed toward valid transactions versus fraudulent ones. One key takeaway from analyzing this dataset based from the histogram is that it is very unbalanced.

Algorithms and Techniques

Unsupervised Outlier Detection using Local Outlier Factor (LOF)

The anomaly score of each sample is called Local Outlier Factor. It measures the local deviation of density of a given sample with respect to its neighbors. It is local in that the anomaly score depends on how isolated the object is with respect to the surrounding neighborhood. More precisely, locality is given by k-nearest neighbors, whose distance is used to estimate the local density. By comparing the local density of a sample to the local densities of its neighbors, one can identify samples that have a substantially lower density than their neighbors. These are considered outliers.

Isolation Forest Algorithm

The IsolationForest 'isolates' observations by randomly selecting a feature and then randomly selecting a split value between the maximum and minimum values of the selected feature.

Since recursive partitioning can be represented by a tree structure, the number of splittings required to isolate a sample is equivalent to the path length from the root node to the terminating node.

This path length, averaged over a forest of such random trees, is a measure of normality

and our decision function.

Random partitioning produces noticeably shorter paths for anomalies. Hence, when a

forest of random trees collectively produce shorter path lengths for particular samples,

they are highly likely to be anomalies.

Benchmark

This dataset was obtained from Kaggle and based upon my observation the accuracy,

f1-score, and recall shouldn't lesser than 75%. Otherwise, this would be a poor model

falling short of other credit card fraud detection models in the data science space.

Methodology

Data Preprocessing

The first data preprocessing tactic I performed was normalizing the Amount Column.

Then, I performed SVM algorithm on the unbalanced dataset to combat unbalanced

classes within the dataset.

6

Implementation

The chosen tactic used on the data distribution needed to split evenly across the valid and fraud classes to ratio of 50% for each class. Thus, the chosen tactic was under-sampling which included shuffling to insure minimal information loss occurred. Thus, I went on to perform the algorithms on the dataset.

Refinement

The model fitting was used to create a simplified representation of the data. The prediction values were reshaped to 0 for valid and 1 for Fraud. Thus, the classifications are processed and generates a simplified representation of both algorithms in the outputted code cells.

Results

Model Evaluation and Validation

The model that won was Isolation Forest algorithm. Why so? This selected model obtained 0.35 in precision, recall, and F1-score across. While Local Outlier Factor Algorithm obtained 0.05 in precision, recall, and F1-score. Thus, Isolation Forest

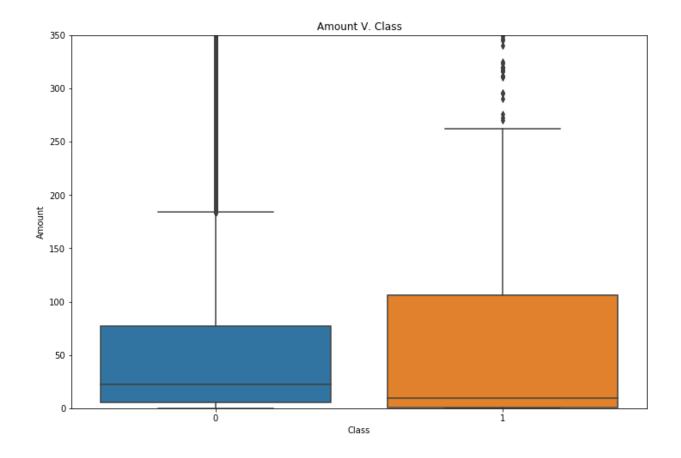

Algorithm was selected for having the best results. This model is not ready to detect credit card fraud just yet.

Justification

The model that was designed with the Isolation Forest Algorithm obtained 0.35% in precision, recall, and F1-score. On the other hand, Local Outlier Factor Algorithm obtained 0.05% in precision, recall, and F1-score. All in all, none of these models are quit yet ready to detect credit card fraud.

Conclusion

Free-Form Visualization

The visualization above shows how fraud transaction are in greater amounts than valid transactions. The two classes are 0 for valid transactions and 1 for fraud transactions.

Reflection

The flow of this project started with installing the dependencies. Then the dataset was loaded into the Ipython Notebook(also known as Jupyter Notebooks). From here some quick data analysis was performed using pandas on the data to display to some visualizations. Then the data was preprocessed with normalization and support vector machine. Under-sampling was also used on the dataset with shuffling. Finally, the algorithms were applied on the dataset. The hardest thing about this model was figuring out what parameters to add and tune. I learned that this could also be solved in the future hopefully with a software that can aid in determining what algorithms to use for the dataset.

Improvement

Looking back on the whole process of this project I would say one improvement that could be added is additional complex algorithms. Secondly, adding more data in this model could also improve it greatly.
